The National Institute of Standards and Technology was established in 1988 by Congress to "assist industry in the development of technology needed to improve product quality, to modernize manufacturing processes, to ensure product reliability . . . and to facilitate rapid commercialization . . . of products based on new scientific discoveries."

NIST, originally founded as the National Bureau of Standards in 1901, works to strengthen U.S. industry's competitiveness; advance science and engineering; and improve public health, safety, and the environment. One of the agency's basic functions is to develop, maintain, and retain custody of the national standards of measurement, and provide the means and methods for comparing standards used in science, engineering, manufacturing, commerce, industry, and education with the standards adopted or recognized by the Federal Government.

As an agency of the U.S. Commerce Department's Technology Administration, NIST conducts basic and applied research in the physical sciences and engineering, and develops measurement techniques, test methods, standards, and related services. The Institute does generic and precompetitive work on new and advanced technologies. NIST's research facilities are located at Gaithersburg, MD 20899, and at Boulder, CO 80303. Major technical operating units and their principal activities are listed below. For more information contact the Publications and Program Inquiries Desk, 301-975-3058.

Reports on Information Security Technology

The Information Technology Laboratory (ITL) at the National Institute of Standards and Technology (NIST) promotes the U.S. economy and public welfare by providing technical leadership for the Nation's measurement and standards infrastructure for information technology. ITL develops tests, test methods, reference data, proof of concept implementations and technical analyses to advance the development and productive use of information technology. ITL's responsibilities include the development of technical, physical, administrative, and management standards and guidelines for the cost-effective security and privacy of Sensitive unclassified information in federal computer systems. This Special Publication 800 series reports on ITL's research, guidance, and outreach efforts in computer security, and its collaborative activities with industry, government, and academic organizations.

Abstract

This recommendation defines six modes of operation for use with an underlying symmetric key block cipher algorithm. Five of the modes are confidentiality modes: Electronic Codebook (ECB), Cipher Block Chaining (CBC), Cipher Feedback (CFB), Output Feedback (OFB), and Counter (CTR). This recommendation also defines an authentication mode based on the CBC mode (CBC-MAC). Used with an underlying block cipher algorithm that is approved in a Federal Information Processing Standard (FIPS), the modes in this recommendation can provide cryptographic protection for sensitive, but unclassified, computer data.

KEY WORDS: Authentication, computer security; cryptography; data security; block cipher; encryption; Federal Information Processing Standard; mode of operation.

Table of Contents

Table of Figures

1 Purpose

This publication provides recommendations regarding modes of operation to be used with symmetric key block cipher algorithms.

2 Authority

This document has been developed by the National Institute of Standards and Technology (NIST) in furtherance of its statutory responsibilities under the Computer Security Act of 1997 (Public Law 100-235) and the Information Technology Management Reform Act of 1996, specifically 15 U.S.C. 278 g-3(a)(5). This is not a guideline within the meaning of (15 U.S.C. 278 g-3 (a)(5).

This recommendation is neither a standard nor a guideline, and as such, is neither mandatory nor binding on Federal agencies. Federal agencies and non-government organizations may use this recommendation on a voluntary basis. It is not subject to copyright.

Nothing in this recommendation should be taken to contradict standards and guidelines that have been made mandatory and binding upon Federal agencies by the Secretary of Commerce under his statutory authority. Nor should this recommendation be interpreted as altering or superseding the existing authorities of the Secretary of Commerce, the Director of the Office of Management and Budget, or any other Federal official.

3 Introduction

This recommendation specifies six modes of operation for symmetric key block cipher algorithms, such as the algorithm specified in the proposed Advanced Encryption Standard (AES) [2]. The cryptographic key controls the functioning of the block cipher and, thus, by extension, controls the modes. Because the specification of the block cipher itself is typically made available to the public, cryptographic security depends on the secrecy of the cryptographic key, at a minimum.

The modes in this recommendation are intended for use with any symmetric key block cipher algorithm that is approved by a Federal Information Processing Standard (FIPS). The size of the input blocks to the block cipher algorithm must be the same as the size of the output blocks. A secret cryptographic key must be entered into the device implementing the block cipher algorithm prior to the execution of the mode of operation.

This recommendation specifies five modes that can provide data confidentiality, and one mode that can provide data authentication. The confidentiality modes are the Electronic Codebook (ECB), Cipher Block Chaining (CBC), Cipher Feedback (CFB), Output Feedback (OFB), and Counter (CTR) modes. The authentication mode is the Cipher Block Chaining-Message Authentication Code (CBC-MAC) mode.

This recommendation builds on three FIPS publications that approve modes of operation of two particular FIPS-approved block cipher algorithms. FIPS Pub. 81 [4] specifies the ECB, CBC, CFB, and OFB modes of the Data Encryption Standard (DES). Modes that are essentially equivalent to the CBC-MAC mode of the DES are specified both in the appendix of FIPS Pub. 81 and in FIPS Pub. 113 [5]. FIPS Pub. 46-3 [3] approves the seven modes that are specified in ANSI X9.52 [1]. Four of these modes are equivalent to the ECB, CBC, CFB, and OFB modes with the Triple DES algorithm (TDEA) as the underlying block cipher; the other three modes in ANSI X9.52 are variants of the CBC, CFB, and OFB modes of Triple DES that use interleaving or pipelining.

4 Definitions, Abbreviations, and Symbols

4.1 Definitions and Abbreviations

Authentication Mode	A mode that is used to determine that a message has not been changed since leaving its point of origin. The authentication mode in this recommendation is the CBC-MAC mode.
Bit	A binary digit: 0 or 1.
Bit Error	The substitution of a ‘0’ bit for a ‘1’ bit, or vice versa.
Bit String	An ordered sequence of 0’s and 1’s.
Block Cipher	A family of functions and their inverse functions that is parameterized by cryptographic keys; the functions map bit strings of a fixed length to bit strings of the same length.
Block Size	The number of bits in an input (or output) block of the block cipher.
CBC	Cipher Block Chaining.
CBC-MAC	Cipher Block Chaining-Message Authentication Code
CFB	Cipher Feedback.
Ciphertext	Encrypted data.
Confidentiality Mode	A mode that is used to encipher plaintext and decipher ciphertext. The confidentiality modes in this recommendation are the ECB, CBC, CFB, OFB, and CTR modes.
CTR	Counter
Cryptographic Key	A parameter used in the block cipher algorithm that determines the forward cipher operation and the inverse cipher operation.
Data Block (Block)	A sequence of bits whose length is the block size of the block cipher.
Data Segment (Segment)	In the CFB mode, a sequence of bits whose length is a parameter that does not exceed the block size.

Decryption (Deciphering)	The routine of a confidentiality mode that transforms the ciphertext into the plaintext.
ECB	Electronic Codebook
Encryption (Enciphering)	The routine of a confidentiality mode that transforms the plaintext into the ciphertext.
Exclusive-OR	The bitwise addition, modulo 2, of two bit strings of equal length.
FIPS	Federal Information Processing Standard.
Forward Cipher Function (Forward Cipher Operation)	One of the two functions of the block cipher algorithm that is selected by the cryptographic key.
Initialization Vector (IV)	A data block independent of the key and the plaintext that is a parameter for the CBC, CFB, and OFB modes.
Input Block	A data block that is an input to either the forward cipher function or the inverse cipher function of the block cipher algorithm.
Inverse Cipher Function (Inverse Cipher Operation)	The function that reverses the transformation of the forward cipher function when the same cryptographic key is used.
Least Significant Bit(s)	The right-most bit(s) of a bit string.
Message Authentication Code (MAC)	The output of an authentication mode of operation.
Mode of Operation (Mode)	An algorithm for the cryptographic transformation of data that features a symmetric key block cipher algorithm.
Most Significant Bit(s)	The left-most bit(s) of a bit string.
Nonce	A value that is used only once.
Octet	A group of eight binary digits.
OFB	Output Feedback.

Output Block	A data block that is an output of either the forward cipher function or the inverse cipher function of the block cipher algorithm.
Plaintext	Usable data.

4.2 Symbols

4.2.1 Variables

b	The block size, in bits.
j	The index to a sequence of data blocks or data segments ordered from left to right.
n	The number of data blocks or data segments in the plaintext.
s	The number of bits in a data segment.
t	The number of bits in a truncated MAC.
u	The number of bits in a partial plaintext or ciphertext block.
C_j	The j^{th} ciphertext block or ciphertext segment.
$\widetilde{C}_n$	A partial ciphertext block.
I_j	The j^{th} input block.
IV	The initialization vector.
K	The secret key.
O_j	The j^{th} output block.
P_j	The j^{th} plaintext block or plaintext segment.
$\widetilde{P}_n$	A partial plaintext block.
T_j	The j^{th} counter that is used in the CTR mode.

4.2.2 Operations and Functions

$X \mid Y$	The concatenation of two bit strings X and Y.

$X \oplus Y$	The bitwise exclusive-OR of two bit strings *X* and *Y* of the same length.
$CIPH_K(X)$	The forward cipher function of the block cipher algorithm under the key *K* applied to the data block *X*.
$CIPH^{-1}_K(X)$	The inverse cipher function of the block cipher algorithm under the key *K* applied to the data block *X*.
$LSB_x(X)$	The bit string consisting of the *x* least significant bits of the bit string *X*.
$MSB_x(X)$	The bit string consisting of the *x* most significant bits of the bit string *X*.
$[x]_2$	The binary representation of the non-negative integer *x*, in a given number of bits.

5 Block Cipher Modes of Operation

The mathematical specifications of the six modes are given in Sections 3.1-3.6, along with descriptions, illustrations, and comments on the potential for parallel processing.

This recommendation assumes that a FIPS-approved symmetric key block cipher algorithm has been chosen as the underlying algorithm, and that a secret, random key, denoted K, has been established for processing the data. The input and output blocks of the block cipher algorithm are assumed to have the same length, called the block size.

A confidentiality mode of operation of the block cipher algorithm consists of two routines that are inverses of each other, encryption and decryption. Encryption is the transformation of a usable message, called the plaintext, into an unreadable form, called the ciphertext; decryption is the transformation that recovers the plaintext from the ciphertext.

For any given key, the underlying block cipher algorithm of the mode also consists of two functions that are inverses of each other. These two functions are often called encryption and decryption, but in this recommendation, those terms are reserved for the routines of the confidentiality modes. Instead, as part of the choice of the block cipher algorithm, one of the two functions is designated as the forward cipher function, denoted $CIPH_K$; the other function is then called the inverse cipher function, denoted $CIPH^{-1}_K$. The inputs and outputs of both functions are called input blocks and output blocks.

For all of the modes in this recommendation except the CFB mode, the plaintext is represented as a sequence of bit strings called data blocks, whose length is the block size. For the CFB mode, the plaintext is represented as a sequence of bit strings called data segments, whose length is a predetermined parameter that does not exceed the block size. The formatting of the plaintext, including any padding bits that are appended to form complete data blocks or data segments, is outside the scope of this recommendation; see Appendix A for a brief discussion of padding.

For the confidentiality modes in this recommendation, the encryption process transforms each data block or segment of the plaintext into a corresponding data block or segment of the ciphertext. Thus, the ciphertext is a sequence of data blocks or segments. Let n represent the number of data blocks, or, for the CFB mode, the number of data segments, in the plaintext. In the specifications of the modes, the plaintext blocks (or segments) are denoted P_1, P_2, …, P_n, and the corresponding ciphertext blocks (or segments) are denoted C_1, C_2,…, C_n.

The authentication mode in this recommendation, CBC-MAC, is applied to the entire plaintext to produce a single value called the message authentication code (MAC), denoted MAC.

Some of the modes require, in addition to the plaintext, a data block called an initialization vector (IV), denoted IV. The IV does not have to be secret.

The concatenation operation on bit strings is denoted | ; for example, 001 | 10111 = 00110111.

The functions LSB_s and MSB_s return the s least significant bits and the s most significant bits of their arguments. For example, $LSB_3(111011010) = 010$, and $MSB_4(111011010) = 1110$.

Given bit strings of equal length, the exclusive-OR operation, denoted $\oplus$, specifies the addition, modulo 2, of the bits in each bit position, without carries. For example, $10011 \oplus 10101 = 00110$.

Given a non-negative (decimal) integer x, the binary representation of x in a given number of bits is denoted by $[x]_2$. For example, as an 8 bit string, $[45]_2 = 00101101$.

5.1 The Electronic Codebook Mode

The Electronic Codebook (ECB) mode is a confidentiality mode that is defined as follows:

ECB Encryption: $C_j = CIPH_K(P_j)$ for $j = 1 \ldots n$.

ECB Decryption: $P_j = CIPH^{-1}_K(C_j)$ for $j = 1 \ldots n$.

In ECB encryption, the forward cipher function is applied directly, and independently, to each block of the plaintext. The resulting sequence of output blocks is the ciphertext.

In ECB decryption, the inverse cipher function is applied directly, and independently, to each block of the ciphertext. The resulting sequence of output blocks is the plaintext.

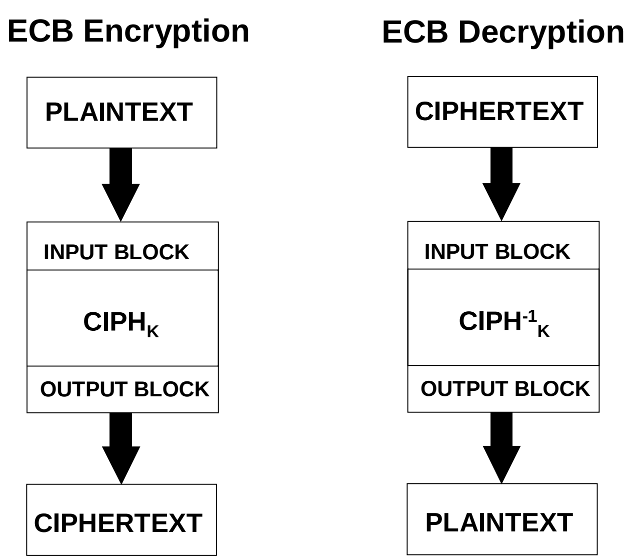

Figure 1: The ECB Mode

In ECB encryption and ECB decryption, multiple forward cipher functions and inverse cipher functions can be computed in parallel.

In the ECB mode, under a given key, a given plaintext block always gets encrypted as the same ciphertext block. If this property is undesirable in a particular application, the ECB mode should not be used.

The ECB mode is illustrated in Figure 1.

5.2 The Cipher Block Chaining Mode

The Cipher Block Chaining (CBC) mode is a confidentiality mode that requires an IV whose integrity should be protected, as discussed in Appendix D. The CBC mode is defined as follows:

CBC Encryption:

$$C_1 = CIPH_K(P_1 \oplus IV);$$
$$C_j = CIPH_K(P_j \oplus C_{j-1}) \qquad \text{for } j = 2 \ldots n.$$

CBC Decryption:

$$P_1 = CIPH^{-1}_K(C_1) \oplus IV;$$
$$P_j = CIPH^{-1}_K(C_j) \oplus C_{j-1} \qquad \text{for } j = 2 \ldots n.$$

In CBC encryption, the first input block is formed by exclusive-ORing the first block of the plaintext with the IV. The forward cipher function is applied to the first input block, and the resulting output block is the first block of the ciphertext. This output block is also exclusive-ORed with the second plaintext data block to produce the second input block, and the forward cipher function is applied to produce the second output block. This output block, which is the second ciphertext block, is exclusive-ORed with the next plaintext block to form the next input block. All of the successive plaintext blocks are “chained” in this way with the previous output/ciphertext blocks to produce the input blocks. The forward cipher function is applied to each input block to produce the ciphertext blocks.

In CBC decryption, the inverse cipher function is applied to the first ciphertext block, and the resulting output block is exclusive-ORed with the initialization vector to recover the first plaintext block. The inverse cipher function is also applied to the second ciphertext block, and the resulting output block is exclusive-ORed with the first ciphertext block to recover the second plaintext block. In general, to recover any plaintext block (except the first), the inverse cipher function is applied to the corresponding ciphertext block, and the resulting block is exclusive-ORed with the previous ciphertext block.

In CBC encryption, the input block to each forward cipher operation (except the first) depends on the result of the previous forward cipher operation, so the forward cipher operations cannot be performed in parallel. In CBC decryption, however, the input blocks for the inverse cipher function, i.e., the ciphertext blocks, are immediately available, so that multiple inverse cipher operations can be performed in parallel.

In the CBC mode under a given key, if a fixed IV is used to encrypt two plaintexts in which the initial blocks P_1, P_2,…, P_j are equal, for any integer j, then the corresponding ciphertext blocks will also be equal. If this property is undesirable in a particular application, then one remedy is to use unique IVs; another remedy is to incorporate a unique string for each message, such as a message identifier, into the first plaintext block.

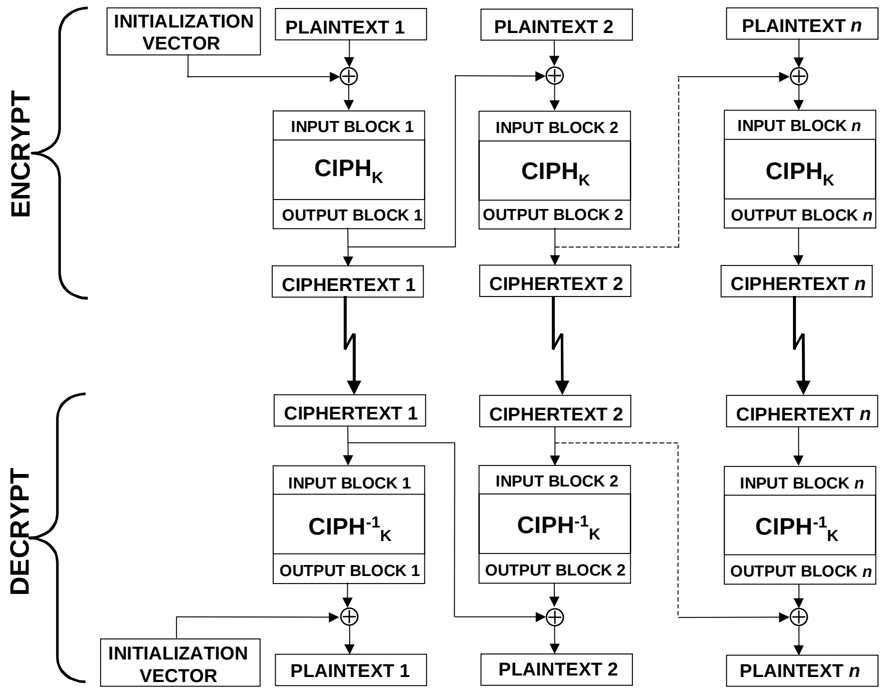

Figure 2: The CBC Mode

The CBC mode is illustrated in Figure 2.

5.3 The Cipher Feedback Mode

The Cipher Feedback (CFB) mode is a confidentiality mode that requires an IV and an integer parameter, denoted *s*, such that $1 \leq s \leq b$. In this mode, each plaintext segment (P_j) and ciphertext segment (C_j) consists of *s* bits. The value of *s* is sometimes incorporated into the name of the mode, as in the following three examples: the 1-bit CFB mode, the 8-bit CFB mode, and the *s*-bit CFB mode. The CFB mode is defined as follows:

CFB Encryption:

$I_1 = IV;$
$I_j = LSB_{b-s}(I_{j-1}) \mid C_{j-1}$ for $j = 2 \ldots n$;
$O_j = CIPH_K(I_j)$ for $j = 1, 2 \ldots n$;
$C_j = P_j \oplus MSB_s(O_j)$ for $j = 1, 2 \ldots n$.

CFB Decryption:

$I_1 = IV;$
$I_j = LSB_{b-s}(I_{j-1}) \mid C_{j-1}$ for $j = 2 \ldots n$;
$O_j = CIPH_K(I_j)$ for $j = 1, 2 \ldots n$;
$P_j = C_j \oplus MSB_s(O_j)$ for $j = 1, 2 \ldots n$.

In CFB encryption, the first input block is the IV, and the forward cipher operation is applied to the IV to produce the first output block. The first ciphertext segment is produced by exclusive-

ORing the first plaintext segment with the segment of the *s* most significant bits of the first output block. (The remaining *b-s* bits of the first output block are discarded.) The *b-s* least significant bits of the IV are then concatenated with the *s* bits of the first ciphertext segment to form the second input block. An alternative description of the formation of the second input block is that the bits of the first input block circularly shift *s* positions to the left, and then the ciphertext segment replaces the *s* least significant bits of the result.

The process is repeated with the successive input blocks until a ciphertext segment is produced from every plaintext segment. In general, each successive input block is enciphered to produce an output block. The segment of the *s* most significant bits of each output block is exclusive-ORed with the corresponding plaintext segment to form a ciphertext segment. Each ciphertext segment (except the last one) is "fed back" into the least significant bits of the previous input block, as described above, to form a new input block. The feedback can be described in terms of the individual bits in the strings as follows: if $i_1 i_2 \ldots i_b$ is the *j*th input block, and $c_1 c_2 \ldots c_s$ is the *j*th ciphertext, then the $(j+1)^{\text{th}}$ input block is $i_{s+1} i_{s+2} \ldots i_b\ c_1 c_2 \ldots c_s$.

In CFB decryption, the IV is the first input block, and each successive input block is formed as in CFB encryption, by concatenating the *b-s* least significant bits of the previous input block with the *s* most significant bits of the previous ciphertext. The *forward cipher* function is applied to each input block to produce the output blocks. The segments of the *s* most significant bits of the output blocks are exclusive-ORed with the corresponding ciphertext segments to recover the plaintext segments.

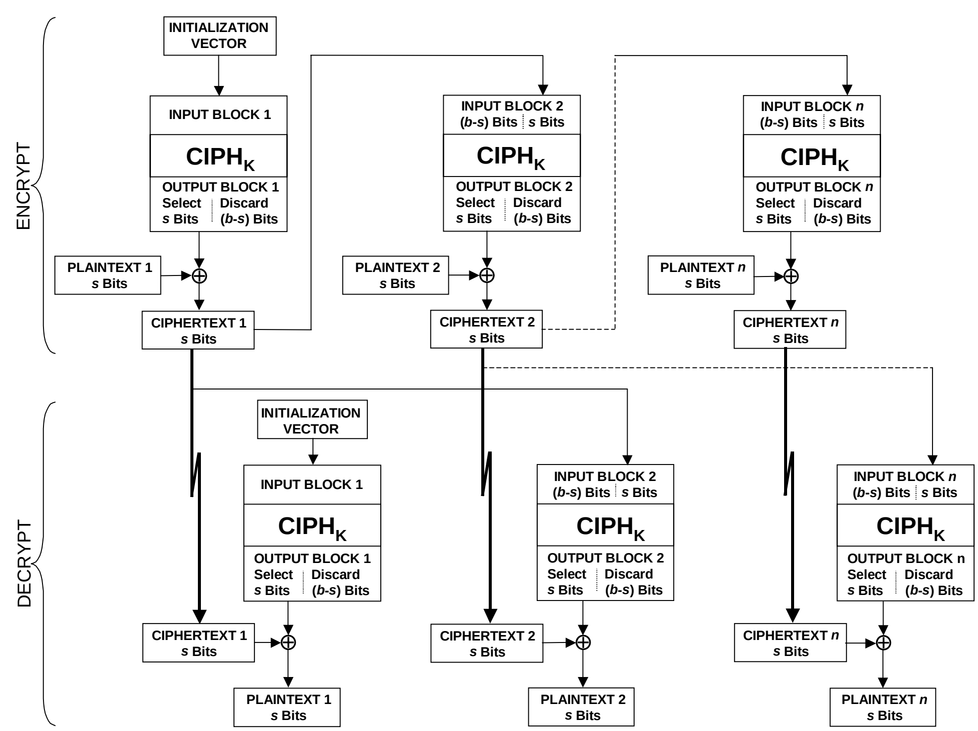

Figure 3: The CFB Mode

In CFB encryption, like CBC encryption, the input block to each forward cipher function (except the first) depends on the result of the previous forward cipher function; therefore, multiple forward cipher operations cannot be performed in parallel. In CFB decryption, the required forward cipher operations can be performed in parallel, if the input blocks are first constructed (in series) from the IV and the ciphertext.

In the CFB mode under a given key, if a fixed IV is used to encrypt two plaintexts in which the initial segments P_1, P_2,…, P_j are equal, for any integer j, then the corresponding ciphertext segments will also be equal. If this property is undesirable in a particular application, then one remedy is to use unique IVs; another remedy is to incorporate a unique string for each message, such as a message identifier, into the first plaintext block.

The CFB mode is illustrated in Figure 3.

5.4 The Output Feedback Mode

The Output Feedback (OFB) mode is a confidentiality mode that requires a unique IV for every message that is ever encrypted under the given key. The OFB mode is defined as follows:

OFB Encryption:	$I_1 = IV;$	
	$I_j = O_{j-1}$	for $j = 2 \ldots n$;
	$O_j = CIPH_K(I_j)$	for $j = 1, 2 \ldots n$;
	$C_j = P_j \oplus O_j$	for $j = 1, 2 \ldots n$.
OFB Decryption:	$I_1 = IV;$	
	$I_j = O_{j-1}$	for $j = 2 \ldots n$;
	$O_j = CIPH_K(I_j)$	for $j = 1, 2 \ldots n$;
	$P_j = C_j \oplus O_j$	for $j = 1, 2 \ldots n$.

In OFB encryption, the IV is transformed by the forward cipher function to produce the first output block. The first output block is exclusive-ORed with the first plaintext block to produce the first ciphertext block. The first output block is then transformed by the forward cipher function to produce the second output block. The second output block is exclusive-ORed with the second plaintext block to produce the second ciphertext block, and the second output block is transformed by the forward cipher function to produce the third output block. Thus, the successive output blocks are produced from enciphering the previous output blocks, and the output blocks are exclusive-ORed with the corresponding plaintext blocks to produce the ciphertext blocks.

In OFB decryption, the IV is transformed by the *forward cipher* function to produce the first output block. The first output block is exclusive-ORed with the first ciphertext block to recover the first plaintext block. The first output block is then transformed by the forward cipher function to produce the second output block. The second output block is exclusive-ORed with the second ciphertext block to produce the second plaintext block, and the second output block is also transformed by the forward cipher function to produce the third output block. Thus, the successive output blocks are produced from enciphering the previous output blocks, and the output blocks are exclusive-ORed with the corresponding ciphertext blocks to recover the plaintext blocks.

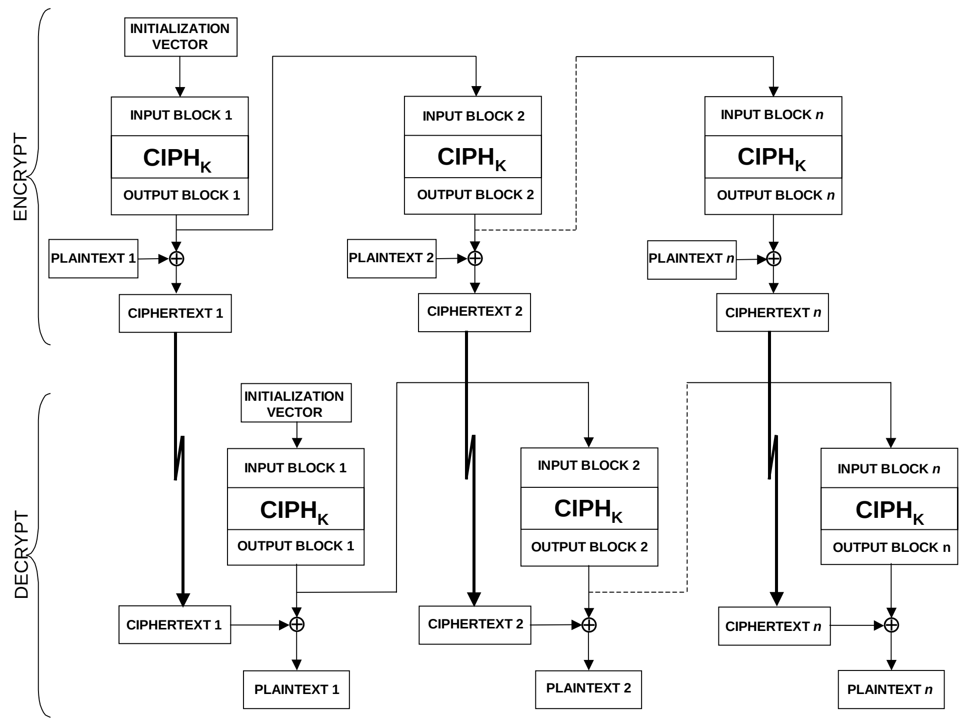

Figure 4: The OFB Mode

In both OFB encryption and OFB decryption, each forward cipher function (except the first) depends on the results of the previous forward cipher function; therefore, multiple forward cipher functions cannot be performed in parallel. However, if the IV is known, the output blocks can be generated prior to the availability of the plaintext or ciphertext data.

The OFB mode requires a unique IV for every message that is ever encrypted under the given key. If, contrary to this requirement, the same IV is used for the encryption of more than one message, then the confidentiality of those messages may be compromised. In particular, if a plaintext block of any of these messages is known, say, the *j*th plaintext block, then the *j*th output of the forward cipher function can be determined easily from the *j*th ciphertext block of the message. This information allows the *j*th plaintext block of any other message that is encrypted using the same IV to be easily recovered from the *j*th ciphertext block of that message.

Confidentiality may similarly be compromised if *any* of the input blocks to the forward cipher function for the encryption of a message is used as the IV for the encryption of another message under the given key.

The OFB mode is illustrated in Figure 4.

5.5 The Counter Mode

The Counter (CTR) mode is confidentiality mode that requires a sequence of blocks, called counters, with the property that each block in the sequence is different than every other block. This condition is not restricted to a single message: across all of the messages that are encrypted under the given key, all of the counters must be distinct. In this recommendation, the counters are denoted T_1, T_2, … , T_n. Methods for generating counters are discussed in Appendix B. Given a sequence of counters, T_1, T_2, … , T_n, the CTR mode is defined as follows:

CTR Encryption: $O_j = CIPH_K(T_j)$ for $j = 1, 2 \ldots n$;
$C_j = P_j \oplus O_j$ for $j = 1, 2 \ldots n$.

CTR Decryption: $O_j = CIPH_K(T_j)$ for $j = 1, 2 \ldots n$;
$P_j = C_j \oplus O_j$ for $j = 1, 2 \ldots n$.

In CTR encryption, the counters are each transformed by the forward cipher function, and the resulting blocks are exclusive-ORed with the corresponding plaintext blocks to produce the ciphertext blocks.

In CTR decryption, the counters are each transformed by the *forward cipher* function, and the resulting blocks are exclusive-ORed with the corresponding ciphertext blocks to recover the plaintext blocks.

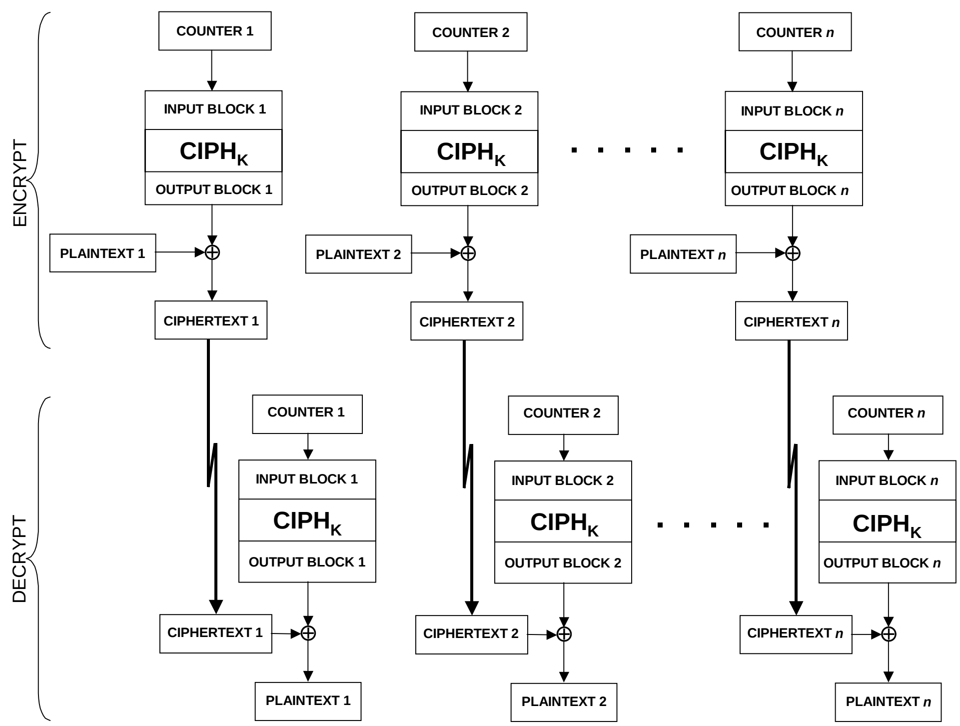

Figure 5: The CTR Mode

In both CTR encryption and CTR decryption, the forward cipher functions can be performed in parallel; similarly, the plaintext block that corresponds to any particular ciphertext block can be recovered independently from the other plaintext blocks, if the corresponding counter block can be determined. Moreover, the forward cipher functions can be applied to the counters prior to the availability of the plaintext or ciphertext data.

The CTR mode is illustrated in Figure 5.

5.6 The Cipher Block Chaining-Message Authentication Code Mode

The Cipher Block Chaining-Message Authentication Code (CBC-MAC) mode is an authentication mode that requires a secret key that is distinct from any key used for encryption. Moreover, every plaintext that is authenticated using the CBC-MAC mode under a given key should consist of the same number of blocks, *n*; the value of *n* may vary for different keys. The CBC-MAC mode is defined as follows:

CBC-MAC Generation:
$$O_1 = CIPH_K(P_1);$$
$$O_j = CIPH_K(P_j \oplus O_{j-1}) \qquad \text{for } j = 2 \ldots n;$$
$$MAC = O_n.$$

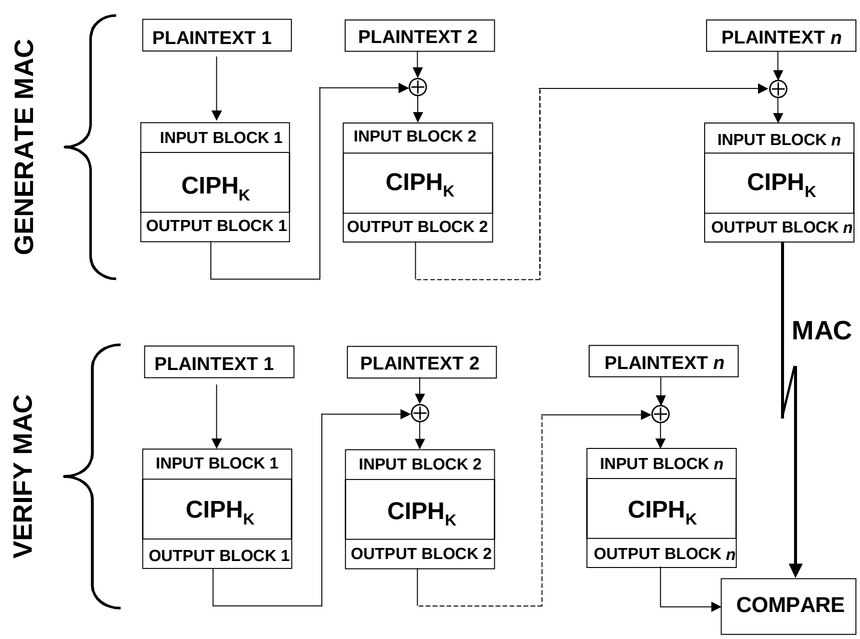

Figure 6: The CBC-MAC Mode

In CBC-MAC generation, output blocks corresponding to each plaintext block are generated in essentially the same manner as the ciphertext blocks in CBC encryption, described in Section 3, omitting the IV (equivalently, the IV can be considered to be the “zero block”, consisting of all ‘0’ bits). The MAC is the final output block.

For CBC-MAC verification, the verifying party generates the CBC-MAC as described above, and then compares the result to the received MAC value. If the MAC values are the same, then the verification is successful, and the data is considered to be authentic; a limitation of this conclusion is discussed in Appendix C. If the MAC values do not match, then the verification is unsuccessful.

As in the case of CBC encryption, defined in Section 3.2, the CBC-MAC mode does not allow the forward cipher operations to be performed in parallel, because the input block to any forward cipher operation depends on the results of the previous operation.

For some applications, it may be desirable to truncate the output, O_n, of the CBC-MAC mode, so that its length in bits, denoted t, is less than the block length. To obtain the truncated MAC, the above definition of MAC is replaced with the following: $MAC=MSB_t(O_n)$. In general, this recommendation requires that $b/2 \leq t \leq b$. For some applications, discussed in Appendix C, the restriction on t may be relaxed to $32 \leq t \leq b$.

The CBC-MAC mode is illustrated in Figure 6.

Appendix A: Padding

The following formatting size requirement applies to each mode in this recommendation: the plaintext must be a sequence of complete data blocks (or, for CFB mode, data segments). In other words, the total number of bits in the data string that represents the formatted message must be an integer multiple of the block (or segment) size. Any partial data block (or segment) will require special handling within each particular application.

For the OFB and CTR modes, the special handling can be achieved by a straightforward modification of the mode. In particular, suppose that a message consists of n-1 full plaintext blocks, P_1, P_2, …, P_{n-1}, followed by a partial plaintext block, denoted $\tilde{P}_n$, that consists of u bits, where $1 \leq u < b$. The specifications of both OFB and CTR encryption are modified by replacing the formula for the last ciphertext block C_n with the following formula for a partial ciphertext block, denoted $\tilde{C}_n$, that also consists of u bits: $\tilde{C}_n = \tilde{P}_n \oplus MSB_u(O_n)$; the rest of the specifications are unchanged. The specifications of both OFB and CTR decryption are modified by replacing the formula for P_n with the following formula: $\tilde{P}_n = \tilde{C}_n \oplus MSB_u(O_n)$. The rest of the specifications for OFB and CTR decryption are unchanged.

If the application permits the number of bits in the message to expand, then the special handling may be to append extra bits, called padding, to complete the block (or segment). Three examples of padding methods are presented in this appendix. Under each of the methods, the padding bits can be removed unambiguously, provided the receiver can determine that the message is indeed padded. One way to ensure that the receiver does not mistakenly remove bits from an unpadded message is to require the sender to pad every message, including messages that already satisfy the formatting size requirement. For such messages, an entire block (or segment) of padding is appended. Alternatively, such messages can be sent without padding, if, for every message, the existence of padding is communicated in some way.

In the first method, the data string is padded at the trailing end with the complement of the trailing bit of the unpadded message: if the trailing bit is ‘1,’ then ‘0’ bits are appended, and if the trailing bit is ‘0,’ then ‘1’ bits are appended. As few bits are added as are necessary to meet the formatting size requirement.

In the second method, the data string is padded at the trailing end with a single ‘1’ bit, and the resulting string is padded at the trailing end by as few ‘0’ bits (possibly none) as are necessary to meet the formatting size requirement.

In the third method, taken from RFC 2630 [6], there is redundancy in the padding. Let B be the number of octets in the data blocks (or segments) and let L be the number of octets in the data string. The data string is padded at the trailing end with B-(L mod B) octets, each of which is the binary representation of B-(L mod B). In other words, the input is padded at the trailing end with one of the following strings:

00000001	if L mod $B = B$-1

00000010 00000010					if L mod B = B –2
00000011 00000011 00000011					if L mod B = B –3
00000100 00000100 00000100 00000100					if L mod B = B –4
⋮					
$[B\text{-}1]_2$ $[B\text{-}1]_2$	…	$[B\text{-}1]_2$		(B-1 octets)	if L mod B = 1
$[B]_2$ $[B]_2$	…	$[B]_2$	$[B]_2$	(B octets)	if L mod B = 0,

where $[B]_2$ and $[B\text{-}1]_2$ are the binary representations of B and B-1 as octets. There are two conditions for using this method: the data blocks (or segments) and the data string must be expressible in octets, i.e., their lengths in bits are a multiple of 8, and B must satisfy $2 \leq B \leq 256$.

Appendix B: Generation of Counter Blocks

The specification of the CTR mode requires a unique counter block for each plaintext block that is ever encrypted under a given key, across all messages. If, contrary to this requirement, a counter block is used repeatedly, then the confidentiality of all of the plaintext blocks corresponding to that counter block may be compromised. In particular, if any plaintext block that is encrypted using a given counter block is known, then the output of the forward cipher function can be determined easily from the associated ciphertext block. This output allows any other plaintext blocks that are encrypted using the same counter block to be easily recovered from their associated ciphertext blocks.

There are two aspects to satisfying the uniqueness requirement. First, an incrementing function for generating the counters blocks from any initial counter block can ensure counter blocks do not repeat within a given message. Second, the initial counter blocks, T_1, must be chosen to ensure that counters are unique across all messages that are encrypted under the given key.

B.1 The Standard Incrementing Function

In general, given the initial counter block for a message, the successive counter blocks are derived by applying an incrementing function. Let n be the number of blocks in the given plaintext message, and b is the number of bits in the block.

The standard incrementing function can apply either to an entire block or to a part of a block. Let m be the number of bits in the specific part of the block to be incremented, so that m is a positive integer such that $m \le b$. Any string of m bits can be regarded as the binary representation of a non-negative integer x that is strictly less than 2^m. The standard incrementing function takes $[x]_2$, the binary representation of x in m bits, and returns $[x+1 \bmod 2^m]_2$, the binary representation in m bits of the following integer, x+1, modulo 2^m.

For example, let the standard incrementing function apply to the five least significant bits of eight bit blocks, so that b=8 and m=5 (unrealistically small values); let * represent each unknown bit in this example, and let ***11110 represent a block to be incremented. The following sequence of blocks results from four applications of the standard incrementing function:

```
* * * 1 1 1 1 0
* * * 1 1 1 1 1
* * * 0 0 0 0 0
* * * 0 0 0 0 1
* * * 0 0 0 1 0.
```

Counter blocks in which a given set of m bits are incremented by the standard incrementing function satisfy the uniqueness requirement *within the given message* provided that $n \le 2^m$. Whether the uniqueness requirement for counter blocks is satisfied across all messages that are encrypted under a given key then depends on the choices of the initial counter blocks for the messages, discussed in the next section.

This recommendation permits the use of any other incrementing function that generates n unique strings of m bits in succession from the allowable initial strings. For example, if the initial string of m bits is not the "zero" string, i.e., if it contains at least one '1' bit, then an incrementing function can be constructed from a linear feedback shift register that is specialized to ensure a sufficiently large period; see Ref. [7] for information about linear feedback shift registers.

B.2 Choosing Initial Counter Blocks

The initial counter blocks, T_1, for each message that is encrypted under the given key must be chosen in a manner than ensures the uniqueness of all the counter blocks across all the messages. Two examples of approaches to choosing the initial counter blocks are given in this section.

In the first approach, for a given key, all plaintext messages are encrypted sequentially. Within the messages, the same fixed set of m bits of the counter block is incremented by the standard incrementing function. The initial counter block for the initial plaintext message may be any string of b bits. The initial counter block for any subsequent message can be obtained by applying the standard incrementing function to the fixed set of m bits of the final counter block of the latest message. In effect, all of the plaintext messages that are ever encrypted under the given key are concatenated into a single message; consequently, the total number of plaintext blocks must not exceed 2^m. Procedures should be established to ensure the maintenance of the state of the final counter block of the latest encrypted message, and to ensure the proper sequencing of the messages.

A second approach to satisfying the uniqueness property across messages is to assign to each message a unique string of $b/2$ bits (rounding up, if b is odd), in other words, a message nonce, and to incorporate the message nonce into every counter block for the message. The leading $b/2$ bits (rounding up if b is odd) of each counter block would be the message nonce, and the standard incrementing function would be applied to the remaining m bits to provide an index to the counter blocks for the message. Thus, if N is the message nonce for a given message, then the jth counter block is given by $T_j = N \mid [j]_2$, where $[j]_2$ is the binary representation of j in m bits, for $j = 1 \ldots n$. The number of blocks, n, in any message must satisfy $n<2^m$. A procedure should be established to ensure the uniqueness of the message nonces.

This recommendation allows other methods and approaches for achieving the uniqueness property. Validation that an implementation of the CTR mode conforms to this recommendation will typically include an examination of the procedures for assuring the uniqueness of counter blocks within messages and across all messages that are encrypted under a given key.

Appendix C: A Limitation of MAC Algorithms

The successful CBC-MAC verification of a MAC does not completely guarantee that the accompanying message is authentic: there is a chance that a source with no knowledge of the key can present a purported MAC on the plaintext message that will pass the verification procedure. For example, an arbitrary purported MAC of t bits on an arbitrary plaintext message may be successfully verified with an expected probability of $(1/2)^t$. This limitation is inherent in any MAC algorithm.

The limitation is magnified if an application permits a given inauthentic message to be repeatedly presented for verification with different purported MACs. Each individual trial succeeds only with a small probability, $(1/2)^t$; however, for repeated trials, the probability increases that, eventually, one of the MACs will be successfully verified. Similarly, if an application permits a given purported MAC to be presented with different inauthentic messages, then the probability increases that, eventually, the MAC will be successfully verified for one of the messages.

Therefore, in general, if the MAC is truncated, then its length, t, should be chosen as large as is practical, with at least half as many bits as the block size, b. The minimum value for t is relaxed to 32 bits for applications in which the two types of repeated trials that are described in the previous paragraph are sufficiently restricted. For example, the application, or the protocol that controls the application, may monitor all of the plaintext messages and MACs that are presented for verification, and permanently reject any plaintext message or any MAC that is included in sufficiently many unsuccessful trials. Another example occurs when the bandwidth of the communications channel is low enough to preclude sufficiently many trials, of either type.

Appendix D: Error Properties

A bit error is the substitution of a ‘0’ bit for a ‘1’ bit, or vice versa. This appendix contains a discussion of the effects of bit errors in ciphertext blocks (or segments), counter blocks, and IVs on the modes in this recommendation. Insertion or deletion of bits into ciphertext blocks (or segments) is also discussed.

For any confidentiality mode, if there are any bit errors in a single ciphertext block (or segment), then the decryption of that ciphertext block (or segment) will be incorrect, i.e., it will differ from the original plaintext block (or segment). In the CFB, OFB, and CTR modes, the bit error(s) in the decrypted ciphertext block (or segment) occur in the same bit position(s) as in the ciphertext block (or segment); the other bit positions are not affected. In the ECB and CBC modes, a bit error may occur, independently, in any bit position of the decrypted ciphertext block, with an expected error rate of fifty percent, depending on the strength of the underlying block cipher.

For the ECB, OFB, and CTR modes, bit errors within a ciphertext block do not affect the decryption of any other blocks. In the CBC mode, any bit positions that contain bit errors in a ciphertext block will also contain bit errors in the decryption of the succeeding ciphertext block; the other bit positions are not affected. In the CFB mode, bit errors in a ciphertext segment affect the decryption of the next b/s (rounded up to the nearest integer) ciphertext segments. A bit error may occur, independently, in any bit position in the decrypted segments, with an expected error rate of fifty percent.

Similarly, for the CTR mode, if there is a bit error in a counter block, then a bit error may occur, independently, in any bit position of the decryption of the corresponding ciphertext, with an expected error rate of fifty percent.

Bit errors in IVs also affect the decryption process. In the OFB mode, bit errors in the IV affect the decryption of every ciphertext block. In the CFB mode, bit errors in the IV affect, at a minimum, the decryption of the first ciphertext segment, and possibly successive ciphertext segments, depending on the bit position of the rightmost bit error in the IV. (In general, a bit error in the ith most significant bit position affects the decryptions of the first i/s (rounding up) ciphertext segments.) For both the OFB and CFB modes, a bit error may occur, independently, in any bit position of the affected ciphertext blocks (or segments), with an expected error rate of fifty percent. In the CBC mode, if bit errors occur in the IV, then the first ciphertext block will be decrypted incorrectly, and bit errors will occur in exactly the same bit positions as in the IV; the decryptions of the other ciphertext blocks are not affected.

Consequently, for the CBC mode, the decryption of the first ciphertext block is vulnerable to the (deliberate) introduction of bit errors in specific bit positions of the IV if the integrity of the IV is not protected. Similarly, for the OFB and CTR modes, the decryption of any ciphertext block is vulnerable to the introduction of specific bit errors into that ciphertext block if its integrity is not protected. The same property also holds for the ciphertext segments in the CFB mode; however, for every ciphertext segment except the last one, the existence of such bit errors may be detected by their randomizing effect on the decryption of the succeeding ciphertext segment.

Table D.1 summarizes the effects of bit errors in a ciphertext block or IV on the decryption of the ciphertext for each of the five confidentiality modes.

Table D.1: Summary of Effect of Bit Errors on Decryption

Mode	Effect of Bit Errors in C_j	Effect of Bit Errors in the IV
ECB	RBE in the decryption of C_j	Not applicable
CBC	RBE in the decryption of C_j SBE in the decryption of C_{j+1}	SBE in the decryption of C_1
CFB	SBE in the decryption of C_j RBE in the decryption of $C_{j+1},\ldots,C_{j+b/s}$	RBE in the decryption of $C_1, C_2, \ldots, C_j$ for some j between 1 and b/s
OFB	SBE in the decryption of C_j	RBE in the decryption of $C_1, C_2, \ldots, C_n$
CTR	SBE in the decryption of C_j	Not applicable *

RBE: random bit errors, i.e., bit errors occur independently in any bit position with an expected probability of ½.
SBE: specific bit errors, i.e., bit errors occur in the same bit position(s) as the original bit error(s).
* Bit errors in the jth counter block, T_j, result in RBE in the decryption of C_j.

The deletion or insertion of bits into a ciphertext block (or segment) spoils the synchronization of the block (or segment) boundaries; in effect, bit errors may occur in the bit position of the inserted or deleted bit, and in every subsequent bit position. Therefore, the decryptions of the subsequent ciphertext blocks (or segments) will almost certainly be incorrect until the synchronization is restored. When the 1-bit CFB mode is used, then the synchronization is automatically restored b+1 positions after the inserted or deleted bit. For other values of s in the CFB mode, and for the other confidentiality modes in this recommendation, the synchronization must be restored externally.

In the CBC-MAC mode, the MAC verification will fail if there are any bit errors in the received MAC.

Appendix E: Modes of Triple DES

FIPS Pub 46-3 [FIPS 46-3] specifies the Data Encryption Standard (DES) algorithm and approves its three-fold, compound operation that is specified in ANSI X9.52 [1]: the Triple Data Encryption Algorithm (TDEA). Essentially, the TDEA consists of the application of the forward DES algorithm, i.e, DES encryption, under one key, followed by the application of the inverse DES algorithm, i.e., DES decryption, under a second key, followed by the application of the forward DES algorithm under a third key. The TDEA is often called Triple DES.

FIPS Pub 46-3 also approves the seven modes of operation of Triple DES that are specified in ANSI X9.52. Four of those modes are equivalent to modes in this recommendation with the TDEA as the underlying block cipher. In particular, the TECB, TCBC, and TOFB modes in ANSI X9.52 are equivalent to the ECB, CBC, and OFB modes in this recommendation, with the TDEA as the underlying block cipher; the TCFB mode in ANSI X9.52 is equivalent to the CFB mode in this recommendation, with the TDEA as the underlying block cipher, provided that the possible choices of the parameter s (the segment size) are restricted to three values: 1, 8, and 64. The remaining three modes in ANSI X9.52 are TCBC-I, TCFB-P, and TOFB-I; they are mode variants that allow for interleaving or pipelining; this recommendation does not provide analogues of these three modes.

The Triple DES *modes* in ANSI X9.52 should not be used as the underlying block cipher algorithm for the modes in this recommendation. However, the Triple DES *algorithm*, i.e., TDEA, as described above, may be used as the underlying block cipher algorithm for the six modes in this recommendation. Two of the resulting modes of Triple DES are new, i.e., not specified in ANSI X9.52: the CTR mode of the TDEA, and the CBC-MAC mode of the TDEA.

Appendix F: Example Vectors for Modes of Operation of the AES

In this appendix, three examples are provided for each of the modes in this recommendation with the AES [2] as the underlying block cipher: one example is given for each of the allowed key sizes (128, 192, and 256 bits). Some intermediate results are presented. For the five confidentiality modes, examples are provided for both encryption and decryption. Examples are provided for 1-bit, 8-bit, and 128 bit CFB. The plaintext for all but two of these examples is equivalent to the following string of hexadecimal characters, formatted into four 128 bit blocks:

```
6bc1bee22e409f96e93d7e117393172a
ae2d8a571e03ac9c9eb76fac45af8e51
30c81c46a35ce411e5fbc1191a0a52ef
f69f2445df4f9b17ad2b417be66c3710.
```

For the example of 1-bit CFB, the plaintext is the first 16 bits in the above string; for the example of 8-bit CFB, the plaintext is the first 18 octets in the above string. All strings are presented in hexadecimal notation, except in the example of 1-bit CFB, where the plaintext and ciphertext segments are single bits.
